INTRODUCTION

Bruce S. Yare and Associates, Inc. were retained by Stauffer Chemical Company to define hydrogeologic conditions around a closed disposal area at the Chicago Heights, Illinois plant (Figure 1).

From January 8 to 16, 1981, four monitoring wells were installed to increase the areal extent of the existing monitoring well network. The five-inch diameter wells were constructed by drilling 25 to 30 feet to bedrock with a hydraulic rotary rig. Drilling mud was made with bentonite and municipal water. A four-foot long, slotted PVC well screen was attached to steel casing, set in the bottom of the borehole and backfilled with pea gravel. The remaining annulus was filled with neat cement grout. Well development was limited to a short period of air agitation with the rig's compressor.

Information from the monitoring well network, plant production wells, published literature and state records was used to define the water-bearing units and ground-water flow system at the site.

GROUND-WATER OCCURENCE

Glacial Drift

All of northern Illinois is blanketed with unconsolidated sediments deposited by or in front of the numerous ice sheets which once covered the region. These sediments, collectively called glacial drift, consist of till, outwash and glacial lake clays. Tills and glacial lake clays are fine-grained, low permeability sediments. Outwash deposits, composed of sand and gravel, are often important aquifers (Table 1).

Surficial sediments in the vicinity of the plant consist of ground moraine and lake plain (Willman, 1971). Ground moraine is till deposited beneath an ice sheet and a lake plain is a till surface eroded flat by glacial lake wave action.

Regionally-extensive outwash deposits underlie the low permeability till at the site. This sand and gravel deposit is forty feet thick southwest of Chicago Heights, and thins toward the northeast (Prickett and others, 1964). Soil borings indicate these deposits range from less than three to more than twenty feet in thickness beneath the plant (Appendix A.1).

The entire drift sequence recharges the underlying dolomite aquifer at a rate of approximately 300,000 gpd/sq mi (gallons per

Silurian Dolomite Aquifer

A Silurian-age dolomite formation occurs beneath the drift deposits covering the site (Table 1). This dolomite, approximately 400 feet thick, is a regionally-important aquifer tapped by many high-capacity municipal and industrial wells (Figure 1). Individual well yields of over 1000 gpm (gallons per minute) are not uncommon. Ground water occurs mostly under confined, leaky artesian conditions but there are some areas of water table (unconfined) conditions. In the Chicago Heights area, leaky artesian conditions prevail except where heavy pumping has dewatered the upper portion of the aquifer (Figure 2).

Water levels in the dolomite aquifer show a rapid response to recharge from precipitation. However, surficial sediments and/or low permeability beds in the upper part of the dolomite aquifer probably retard downward movement of water toward the main producing zones. Estimates of the aquifer recharge rate range from 177,000 to 225,000 gpd/sq mi (McDonald and Sasman, 1966; Prickett and others, 1964).

Average aquifer transmissivity at the plant is 21,700 gpd/ft (gallons per day per foot) and ranges from 2,000 to 41,000 gpd/ft

reference 9 site name Rughale Chem site id _0.0059446137

(Table 2). The long-term gravity yield of the aquifer is 0.03.

In the past, the Chicago Heights plant relied mainly on the shallow dolomite aquifer to meet its water supply needs (Appendix A.2). Withdrawals from the plant production wells had a noticeable impact on the regional ground-water flow system. In 1966, this pumpage produced a large cone of depression at the plant (Figure 2). The regional flow system was controlled by withdrawals from the Inland Steel and Chicago Heights Municipal well fields located southwest of the plant.

Currently, PW-10 is the only plant production well using the dolomite aquifer as a water supply source. Recent water-level maps for the dolomite aquifer are not available, so the present effects of withdrawals from PW-10 are not known.

Cambro-Ordovician Aquifer

The Cambro-Ordovician aquifer is not a massive water-bearing unit but rather consists of a series of interbedded low-yield dolomite formations and high-yield sandstones. Regionally, the aquifer is very heavily developed with large-scale water supplies obtained from the Ironton-Galesville Sandstone and the Glenwood-St. Peter Sandstone (Table 1). It is not extensively used in the Chicago Heights area (Sasman, 1977), and PW-2 is the only plant production well tapping the Cambro-Ordovician aquifer (Appendix A.3).

Aquifer transmissivity in a municipal well near the plant is

Note: PW-2 which taps the Cambro-Ordovician aquifer was tested in 1942. At a discharge of 680 gallons per minute the specific capacity was reported as 5.3 gpm/ft.

SITE ID DOTT YUGG

1,600 gpd/ft. The average regional storage coefficient is 0.00035 for short time periods and 0.0006 for periods of several years or more (Suter and others, 1959).

A thick confining bed, the Maquoketa Shale, separates the Cambro-Ordovician aquifer from the overlying Silurian dolomite aquifer. The low vertical permeability of the shale (0.00005 gpd/ft²) limits but does not prevent the downward movement of water under natural and pumping-induced gradients. Under a head differential of several hundred feet, the Cambro-Ordovician aquifer receives 1500 gpd/sq mi of recharge from the overlying dolomite aquifer (Prickett and others, 1964).
